The paper at hand presents the principles and methods applied for the impact assessment of the green building portfolio by the mortgage bank (residential and commercial property financing) MünchenerHyp. For further information and the newest published impact report see https://www.mhb.de/de/unternehmen/nachhaltigkeit/esg-und-gruene-anleihen.

1 Rationale for Methodology

MünchenerHyp aims to quantify the potential positive climate effects from green buildings in their portfolio. Green buildings in this context are expected to have a lower energy demand for heating compared to similar buildings of the same type and in the same countries. The selection of eligible buildings is not part of the impact assessment and entirely in the hands of the mortgage bank (in line with their Green Bond Framework 2021 in MünchenerHyp (2022)). However, a second party opinion is available that corroborates the claim that these buildings fulfil the minimum energy standards and exceed them in most cases (ISS ESG, 2022).

The rationale of the impact assessment is that the financing and/or ownership of commercial and residential buildings with low energy demands avoid greenhouse gas emissions, that would otherwise have been emitted from conventional buildings in the overall stock used for the same purpose. Since other stakeholders are involved in this process (other shareholders, owners, rentals), we define this process as "financing potential greenhouse gas reductions". The functional unit is tons CO₂-equivalents (or CO2e) per building and share of financing (1% to 100%). As a normalized unit of comparison, tons CO₂-equivalents (or CO2e) per million € (EUR m) financed are calculated as well. The global warming potential refers to 100 years (GWP 100a) and is calculated with the help of characterization factors for Kyoto-Gases by the IPCC (AR5).

This rationale is in line with current market practices as suggested by the ICMA Green Bond Principles as well as Harmonized Framework for Impact Reporting (ICMA, 2023).

2 Framework

The original input data contains information on the type of buildings and in some cases also the purpose of buildings. Previous impact assessments classified the results according to these building types (e.g., office and storage buildings, or single-family and multi-family homes).

However, the focus of the assessment is to provide the most reliable results which is why a different classification is chosen for the current report (and from 2022 onward). Each building is assigned to 1 out of 4 classes for the quality of data and the resulting calculation:

- Type A: high data quality
- Type B: medium data quality
- Type C: low data quality
- Type D: no data (estimates)

The following sections describe how these data cluster are assigned to the two main asset classes (1) commercial buildings (COM) and (2) residential buildings (RES).
2.1 Matrix for Data Quality

The following table summarizes the input data availability for the four data classes for both commercial (COM) and residential (RES) buildings in the portfolio.

2.2 Calculation for Commercial buildings (COM)

There are 191 contracts in the commercial portfolio that refer to 168 assessable buildings (portfolio until June 2023). These buildings are large and mainly used as offices for rentals. Some of the buildings are also either fully used as storage facilities or consist of large areas that are not heated. The buildings are located in Germany (DE), Austria (AT), Spain (ES), France (FR), United Kingdom (UK), Luxemburg (LU), Netherlands (NL) and the United States (US).

The calculation method for potentially avoided GHG emissions draws on the difference for the energy demand of the building in the portfolio compared to similar buildings in the European and US building stock of office buildings. In opposition to the previous methodology, data now also allows to incorporate other sources of electricity consumption.

If all the relevant data is available, the following equation (\( A_{\text{COM}} \)) is used for Type A buildings:

\[
\text{GHG}_{\text{avoid,COM}} = \left( \frac{\text{FED}_{\text{total}}}{\text{area}_{\text{net-cond}}} \right) - \text{fed}_{\text{stock}} \times \text{ghg}_{\text{carrier}} \times \text{area}_{\text{net-cond}} [\text{kg CO}_2 - \text{equ./building p.a.}] (A_{\text{COM}})
\]

with

- \( \text{GHG}_{\text{avoid,COM}} \): potentially avoided GHG emissions for type A data in [kg CO2e]
- \( \text{FED}_{\text{total}} \): total final energy demand for heating of the building in [kWh]
- \( \text{area}_{\text{net-cond}} \): net-conditioned area of the building in [m²]
- \( \text{fed}_{\text{stock}} \): specific total final energy demand in building stock in [kWh/m²]
- \( \text{ghg}_{\text{carrier}} \): GHG intensity of the energy carrier (heat) with highest GHG-intensity in [kg CO2e/kWh]

We use data from the EU Building Stock Observatory for buildings in EU countries (European Commission, 2023), data from Non-domestic National Energy Efficiency Data-Framework for buildings in the UK (Department for Business, Energy & Industrial Strategy, 2022) as well as data from the Commercial Buildings Energy
Consumption Survey for buildings in the US (U.S. Energy Information Administration, 2018) to derive the average total final energy demand of non-residential buildings in stock \( (f_{\text{stock}}) \).

It is also assumed that primary data on the primary energy demand of the buildings lead to similarly robust results, although additional data is necessary to convert primary energy demand in a country into the final energy demand for the building user. For this purpose, so-called primary-energy-factors or PEFs are used. These factors are energy-carrier specific and were drawn from a short study funded by the European Union (Hitchin et al., 2018).

Equation B\(_{\text{COM}}\) is therefore considered to deliver robust results for Type B data in the following manner.

\[
GHG_{\text{avoid,COM-B}} = \left( \frac{1}{\text{PEF}_{\text{carrier}}} \times \frac{\text{PED}_{\text{total}}}{\text{area}_{\text{net-cond}}} - f_{\text{ed,stock}} \right) \times ghg_{\text{carrier}} \times \text{area}_{\text{net-cond}} \ [\text{kg CO}_2 - \text{equ./ building p. a.}]
\]

\((B_{\text{COM}})\)

with

- \(GHG_{\text{avoid,COM-B}}\): potentially avoided GHG emissions for type B data in \([\text{kg CO}_2\text{e}]\)
- \(\text{PEF}_{\text{carrier}}\): primary energy factor for energy carrier (heat) with highest GHG-intensity in \([\text{kWh/kWh}]\)
- \(f_{\text{ed,stock}}\): specific final energy demand in sampled buildings in specific region in \([\text{kWh/m}^2\text{a}]\)
- \(\text{PED}_{\text{total}}\): primary energy demand of the building in \([\text{kWh}]\)
- \(ghg_{\text{carrier}}\): GHG intensity of the energy carrier (heat) with highest GHG-intensity in \([\text{kg CO}_2\text{e/kWh}]\)

For buildings of type C, only data on the conditioned area and the heating system is available. We assume that these buildings achieve at least a light renovation standard which corresponds to a primary energy demand saving of 16% compared to the building stock (European Commission et al., 2019, p. 24). An additional required variable is the average fraction of the specific final energy demand compared to the specific primary energy demand in the sample (90% for the sample in the current report).

Equation C\(_{\text{COM}}\) shows how primary energy factors (PEFs) are used to estimate the saving in final heat demand when applying that assumption.

\[
GHG_{\text{avoid,COM-C}} = \text{saving}_{\text{ped}} \times f_{\text{ed,stock}} \times \left( \frac{\text{PED}_{\text{sample}}}{\text{ped}_{\text{sample}}} \right) \times ghg_{\text{carrier}} \times \text{area}_{\text{net-cond}} \ [\text{kg CO}_2 - \text{equ./ building p. a.}]
\]

\((C_{\text{COM}})\)

with

- \(GHG_{\text{avoid,COM-C}}\): potentially avoided GHG emissions for type C data in \([\text{kg CO}_2\text{e}]\)
- \(\text{saving}_{\text{ped}}\): primary energy demand saving for light renovation in \([\%]\)
- \(\text{PEF}_{\text{carrier}}\): primary energy factor for energy carrier (heat) with highest GHG-intensity in \([\text{kWh/kWh}]\)
- \(f_{\text{ed,stock}}\): specific final energy demand in sampled buildings in specific region in \([\text{kWh/m}^2\text{a}]\)
- \(\text{PED}_{\text{sample}}\): average final energy demand of buildings in sample which are also provided with a specific primary energy demand in the sample
- \(\text{ped}_{\text{sample}}\): average primary energy demand of buildings in sample which are also provided with a specific final energy demand in the sample
2.3 Method

With the issuer's requirements, each building is assigned a maximum primary energy demand. For buildings of type A, the financing data, primary energy demand, living space, and the type of heating energy carrier (electricity, gas, or none) are available. Although the estimation is line with type C buildings, we assume the most conservative case with electricity being the main heat energy carrier (highest PEF with 2.3). The equation (D\textsubscript{COM}) is therefore very similar.

\[
\text{GHG}_{\text{avoid,COM\textsubscript{-D}}} = \left(\frac{\text{saving}_{\text{ped}}}{\text{PEF}_{\text{electricity}}} - \text{efu} / \text{building p.a.}\right) \times \left(\frac{\text{ed}_{\text{stock}}}{\text{ed}_{\text{sample}}} \times \text{ghg}_{\text{electricity}} \times \text{area}_{\text{net-cond}} \times \text{kg CO}_2\right)
\]

\text{(D\textsubscript{COM})}

with

- \text{GHG}_{\text{avoid,COM\textsubscript{-C}}}: potentially avoided GHG emissions for type C data in [kg CO2e]
- \text{saving}_{\text{ped}}: primary energy demand saving for light renovation in [%]
- \text{PEF}_{\text{electricity}}: primary energy factor for electricity in [kWh/kWh]
- \text{ed}_{\text{stock}}: specific final energy demand in sampled buildings in specific region in [kWh/m²a]
- \text{ed}_{\text{sample}}: average final energy demand of buildings in sample which are also provided with a specific primary energy demand in the sample
- \text{ped}_{\text{sample}}: average primary energy demand of buildings in sample which are also provided with a specific final energy demand in the sample
- \text{ghg}_{\text{electricity}}: GHG intensity of the electricity in [kg CO2e/kWh]

### 2.3 Calculation for Residential Buildings (RES)

There are 8,859 buildings in the input data. They are grouped into the categories single-family house (SFH), multi-family house (MFH) and terrace house (TH). The years of construction range from earlier than 1595 to 2016 and newer. No building has a higher primary energy demand than 70 kWh/a as defined by the issuer's framework or 55 kWh/a if the building was financed after the 1\textsuperscript{st} of May 2020.

For buildings of type A, the financing data, primary energy demand, living space, building type and year of construction are known (no data on final heat demand and heating system). The equation (A\textsubscript{RES}) is considered to deliver the most robust result for impact reporting:

\[
\text{GHG}_{\text{avoid,RES\textsubscript{-A}}} = \frac{\text{ped}_{\text{ref}} - \text{ped}}{\text{PEF}_{\text{gas}}} \times \text{ghg}_{\text{gas}} \times A \times \text{kg CO}_2 - \text{equ.} / \text{building} \quad \text{(A\textsubscript{RES})}
\]

with

- \text{GHG}_{\text{avoid,RES\textsubscript{-A}}}: potentially avoided GHG emissions for type A data in [kg CO2e]
- \text{ped}_{\text{ref}}: specific primary energy demand of building [kWh/m²a]
- \text{ped}: specific primary energy demand of buildings in stock at year of construction [kWh/m²a]
- \text{PEF}_{\text{gas}}: primary energy factor for gas (representing all heating systems)
- \text{ghg}_{\text{gas}}: GHG intensity of gas for heating in [kg CO2e/kWh]
- \text{A}: living space as conditioned area in [m²]

For buildings of type B, only the primary energy demand is known. In accordance with the issuer's requirements, each building is assigned a maximum primary energy demand.
demand of either 70 kWh/a (until 30\textsuperscript{th} of April 2020) or 55 kWh/a (from 1\textsuperscript{st} of May 2020 onward).

The equation (B\textsubscript{RES}) is therefore only slightly altered:

\[
\text{GHG}_{\text{avoid,RES-B}} = \frac{\text{ped}_{\text{max}} - \text{ped}_{\text{min}}}{\text{PF}_{\text{gas}}} \cdot \text{ghg}_{\text{gas}} \cdot A \ [\text{kg CO}_2 - \text{equ./ building}] (B\textsubscript{RES})
\]

with

- \(\text{GHG}_{\text{avoid,RES-B}}\): potentially avoided GHG emissions for type B data in [kg CO\textsubscript{2}eq]
- \(\text{ped}_{\text{max}}\): maximum specific primary energy demand of buildings in portfolio in [kWh/m\textsuperscript{2}]

For buildings of type C, the financing data, the living space and the building type are known. To account for the fact that no suitable reference building can be selected, the lowest primary energy demands for buildings in stock (conservative estimate) are used.

The results from type C buildings are therefore considered to be robust as a conservative estimate (it is unlikely that the actual buildings have higher energy savings) but less accurate:

\[
\text{GHG}_{\text{avoid,RES-C}} = \frac{\text{ped}_{\text{min}}}{\text{PF}_{\text{gas}}} \cdot \text{ghg}_{\text{gas}} \cdot A \ [\text{kg CO}_2 - \text{equ./ building}] (C\textsubscript{RES})
\]

with

- \(\text{GHG}_{\text{avoid,RES-C}}\): potentially avoided GHG emissions for type C data in [kg CO\textsubscript{2}eq]
- \(\text{ped}_{\text{min}}\): lowest specific primary energy demand for building types in stock in [kWh/m\textsuperscript{2}]

Data for buildings of type D, in addition to the restrictions of type C buildings, also lacks information on the living space of the buildings. As this data is available for all other buildings, a cost factor is calculated the allows to estimate the living space. It is drawn from the 3\textsuperscript{rd} quartile of the total costs per square-metre of all other buildings in the sample in order to ensure a conservative estimate for the resulting avoided GHG emissions in equation D\textsubscript{RES}.

\[
\text{GHG}_{\text{avoid,RES-D}} = \frac{\text{ped}_{\text{min}}}{\text{PF}_{\text{gas}}} \cdot \text{ghg}_{\text{gas}} \cdot F \cdot \text{liv}_{\text{sample}} \ [\text{kg CO}_2 - \text{equ./ building}] (D\textsubscript{RES})
\]

with

- \(\text{GHG}_{\text{avoid,RES-D}}\): potentially avoided GHG emissions for type D data in [kg CO\textsubscript{2}eq]
- \(F\): total costs of building in [EUR]
- \(\text{liv}_{\text{sample}}\): financed living space per total costs, 3\textsuperscript{rd} quartile of sample in [m\textsuperscript{2}/EUR]

All equations have been integrated into a calculation script that can be found in the Appendix to this report.
3 Data and Assumptions

3.1 Data and assumptions for commercial building portfolio

The following table summarizes the data sources and assumptions for the calculation of commercial (COM) buildings in the portfolio.

</tr>
</tbody>
</table>

3.3 Limitations of the methodology

All data, assumptions and calculations shown here are suitable to estimate conservative estimates for the avoided GHG emission potentials. The energy savings in the actual buildings compared to buildings in stock are often expected to be larger than shown here and in the impact assessment. It is also likely that many of the residential buildings achieve their low primary energy demands with the help of heating systems other than gas and oil. In these cases, an additional GHG saving effect would have to be considered that is caused by the difference in GHG intensities of the energy carriers (e.g., biomass versus gas).

In terms of overall accuracy, the lack of data for electricity use leads to less accurate results. This affects the primary energy demand of the buildings, as the share of heat and electricity use might differ strongly compared to the building stock. Commercial buildings in particular are also expected to be more electricity-efficient than their counterparts in the building stock, while many residential buildings are equipped with photovoltaic panels for their own electricity production (at less than 50 g CO₂-equivalents per kWh).

Moreover, that stock approach can – and has indeed – led to increased GHG emissions for some buildings in the sample. This is the case when the actual energy demand of a building exceeds the expected energy demand of similar buildings in stock. These values have been included in the calculation and thus led to lower GHG savings overall than a sub-sample of buildings for which only savings are considered.
4 Reference data for comparison with literature

The quantification method results in a number of specific characteristics of both building samples. The specific final heat demand (fhd) for COM and the specific primary energy demand (ped) for RES buildings are documented here (see following table). These values can be compared to literature data (fhd of commercial, ped of residential buildings) to evaluate the energy efficiency of the buildings in the portfolio.

Table 4-1: specific final energy demand (COM) and specific primary energy demand (RES) values in the current sample for comparison with literature

Documentation Impact Reporting MhyP 2023
2023-11-10

1. Load the necessary packages and input data

```r
library(readxl)
library(sapply)
library(plyr)

ghg_factor <- 251.5 x CO2 / kWh
pef <- 1 / 2.9 primary energy factor

# Load the necessary packages and input data

path <- str_split(rstudioapi::getSourceEditorContext()$path, )
input <- read_excel(paste(path,

### Fill missing data

# 2.1 Fill missing data

According to the classification scheme the data gap is filled. Primary energy demand is assumed to be 10 kWh/m²a for " zurückgebaut" in the year 2020. It was before that date, primary energy demand is assumed to be 0 kWh/m²a. Where no data regarding living area is given, the 30% quantile of financing costs per square meter derived from the other classes is used to estimate values for living area.

```
3 Impact assessment

3.1 Impact calculation

The weighted values are calculated by 1) subtracting the primary energy demand of the building from the reference value, 2) multiplying that difference with the living area to retrieve energy savings, 3) multiplying energy savings with a ghg factor. The same procedure is applied to the primary energy demand of the building instead of its difference to a reference value to retrieve total absolute emissions.

Finally, the financial data of these indicators and the impact reduction per unit of financing is calculated.

```r
# primary energy factor
ghg_factor <- 3.1

### Input ###
input     <- input[-c("Jahresprimär-energiebedarf", "Effektivkapital in Vertragswährung")]

### Fill Primary Energy Demand ###
idx_u2020 <- which(input$Laufzeitbeginn <= "2020-04-01 UTC")
idx_a2020 <- which(input$Laufzeitbeginn > "2020-04-01 UTC")

### Reduced per unit financed ###

co2_savings financed <- res$"energy savings financed" / table$"Wohnfläche" / table$"Anteil MHB in %" / table$"Effektivkapital in Vertragswährung" # in g CO2 / EUR
```

3.2 Finalize Result

The data frame is collapsed to summarize the results depending on data quality: columnnames and Columnnames are set.

```r
### Result #########

table$"Absolute emissions financed" <- table$"Absolute emissions financed" / table$"Effektivkapital in Vertragswährung" # in g CO2 / EUR
```
